ARTHUR HARVIN MAYBIN III  
The Geology of the Opawica River Complex Quebec, Canada  
(Under the direction of GILLES O. ALLARD)

The Opawica River Complex is a layered mafic igneous intrusion which cuts Archean volcanic rocks of the Matagami-Chibougamau Greenstone Belt. The volcanic sequence was subsequently intruded by the Opawica River Pluton and then folded into an east-west trending anticline. The exposed portion of the complex is about 15,000 feet thick and over 15 miles long. The complex is divided into two zones: the Anorthosite Zone and the Gabbro-Ferropyroxenite Zone. The volcanics and intrusives were syntectonically affected by low grade (greenschist facies) regional metamorphism believed to be of Kenoran age (~2.7 b.y.).

Mineralogical studies using a petrographic microscope and electron probe microanalyzer indicate that the original cumulus phases were plagioclase and clinopyroxene. Inter-cumulus phases were clinopyroxene, plagioclase, magnetite, and ilmenite.

Major element chemistry and preserved textural relationships indicate that the regional metamorphism was essentially isochemical. Gabbroic rocks from the Opawica River Complex show an increase in FeO with a reciprocal decrease in MgO and suggest that the Opawica River Complex formed as a result of fractional crystallization of a basaltic magma having tholeiitic affinities.

#### ACKNOWLEDGMENTS

The author wishes to thank his major professor, Dr. Gilles O. Allard, for his assistance and advice during the course of this study. Appreciation is also extended to Drs. James A. Whitney and John C. Stormer who critically read this manuscript and provided assistance and advice during chemical analysis. Appreciation also to Dr. R. David Dallmeyer for his assistance in the field and critical review of the manuscript.

Special thanks go to senior field assistants, Roger Aubertin and Pierre Simard, and junior field assistants, Rejean Touchette, Luc Chauvin, Alexander Chaykofsky, and Andre Tremblay.

Support for this study was provided by the Quebec Department of Natural Resources, Mineral Exploration, directed by Dr. Andre Laurin and Mr. Francois Dompierre. Thanks also to Jules Cimon, resident geologist in Chibougamau.

## CHAPTER I

## INTRODUCTION

The study area is situated in the central part of Quebec, Canada. It is bounded by longitudes  $75^{\circ} 25'$  and  $75^{\circ} 46'$  west and latitudes  $49^{\circ} 30'$  and  $49^{\circ} 35'$  north in the Southwest Quarter of Guercheville Township (Plate 1), and the North Half of La Ronde Township (Plate 2). A thick section of Pleistocene glacial till masks the paleotopography and the contact relationships among certain rock units. Polished outcrop surfaces with glacial striae and grooves are common. Bedrock exposure is poor and generally represents less than 1% of the map-area. The area is heavily forested and covered by a carpet of moss. Access to Guercheville Township is limited to float plane and canoe. Logging roads in La Ronde Township enable access to the northern part by automobile.

The area is located in the eastern part of the Superior Province of the Canadian Shield (Figure 1). It is part of the east-trending Matagami-Chibougamau Greenstone Belt which is bordered by the Grenville Province on the east and the Kapskasing Sub-province to the west. This Archean Greenstone Belt is typical of those which characterize the Superior Province and consists of volcanic and

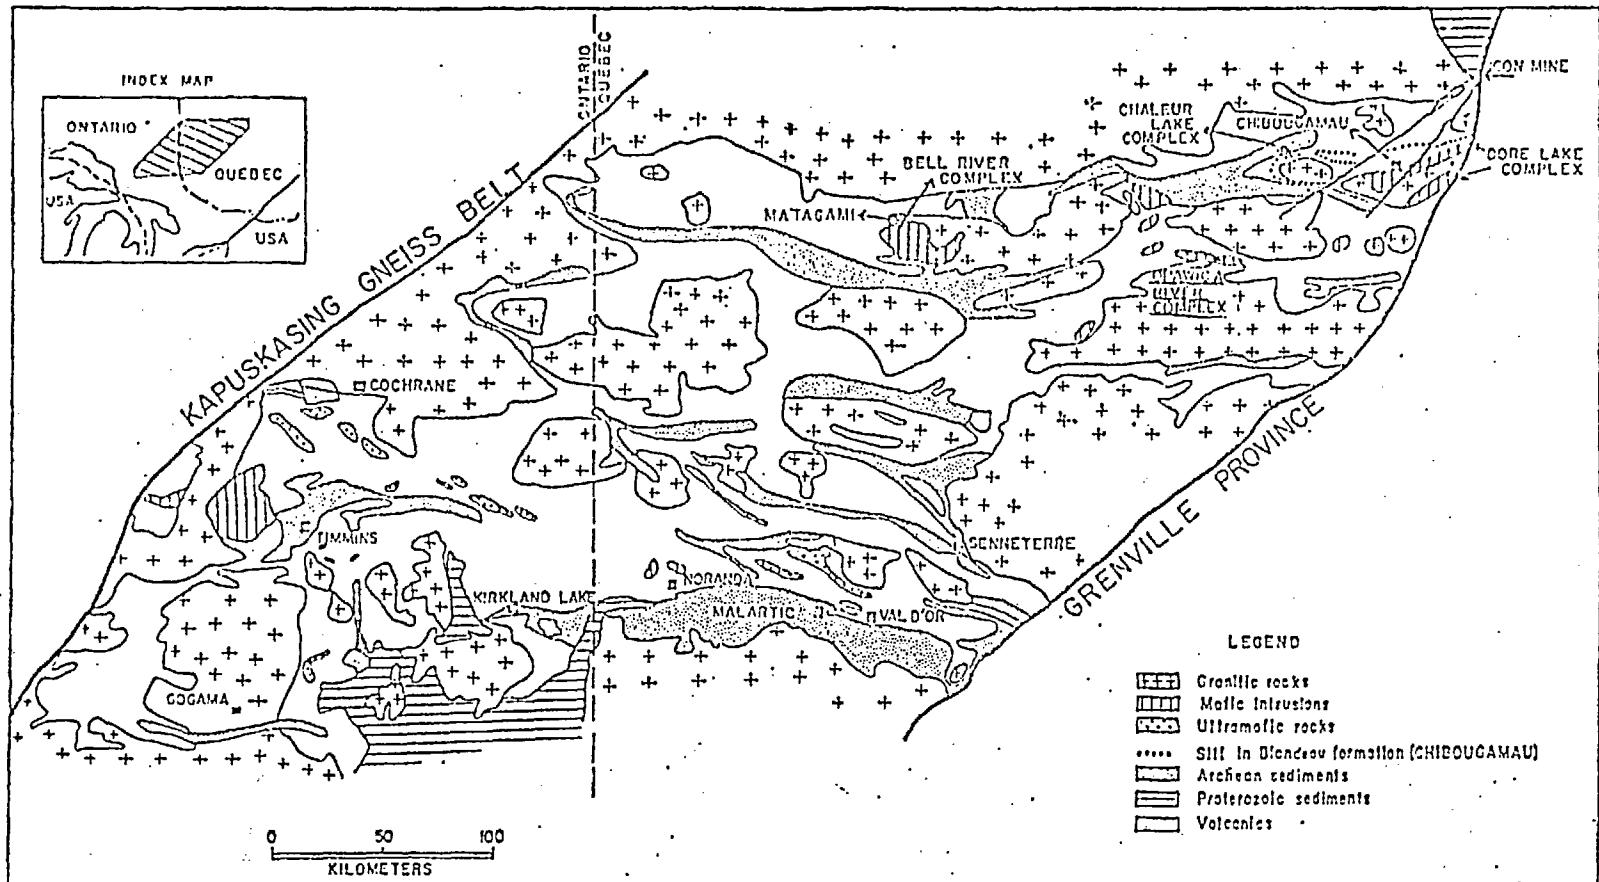

Figure 1. Index map of the Matagami-Chibougamau Greenstone Belt showing location of the Opawica River Complex (study area).

volcaniclastic rocks with intrusive layered mafic complexes and coeval granitic plutons. These rocks were affected by the Kenoran Orogeny dated at 2500 million years by Stockwell (1964) and more recently by Dallmeyer et al. (1975) at between 2650-2700 and 2780-2820 million years. After metamorphism, the north central portion of the study area was intruded by a concentrically zoned granitic pluton.

Previous work in the area was largely reconnaissance in nature and consisted of geologic mapping at a scale of 1:63,360 (Shaw, 1939; Remick, 1955). Present field work consisted of 1:12,000 geologic mapping and detailed petrographic and mineralogical studies.

The purpose of this study is to describe the petrography and chemistry of the rock units in the area. Special attention is given to the Opawica River Complex because of the economic potential of layered mafic intrusions.

## CHAPTER II

### GENERAL GEOLOGY

#### Introduction

In addition to the Opawica River Complex, six lithologic units have been mapped in the study area. The oldest is a greenstone unit, composed principally of intercalated volcanic and volcaniclastic rocks. These lithologies were intruded by the Opawica River Complex and the trondhjemite Opawica River Pluton. This entire sequence was subsequently deformed and metamorphosed. The La Ronde Lake Pluton, a post-kinematic concentrically zoned granitic pluton, intruded the north-central part of the study area. Two other granitic bodies have been defined, however, chronological relationships to other rocks is obscured by glacial drift.

#### Metabasalts

The metabasalts are exposed in the northern portion of the study area (Plates 1 and 2). The basaltic rocks can be divided into two rock types: metabasalts and basaltic metatuffs. Metabasalt is the most abundant type. These rocks typically have a fine grained texture and a light green color. Primary bedding and graded bedding are common in the basaltic metatuffs. Primary volcanic structures

preserved in the metabasalts include pillow structures, scoriaceous flow tops, vesicles, and amygdules. Pillow structures (Figure 2) indicate a submarine origin for these lavas. Scoriaceous flow tops and pillow structures provide excellent top determinations, although pillows are commonly flattened in the plane of tectonic foliation. Metabasalts which lack pillows are distinguished from tuffs by the absence of bedding.

Metabasalts typically exhibit a blastogranular texture whereas the tuffs have a fragmental texture. The dominant minerals are actinolite, plagioclase, epidote, and chlorite. Actinolite ( $z \wedge c = 17$ ) occurs as prisms generally 1 mm in length with a pleochroic formula  $x =$  straw yellow,  $y =$  green, and  $z =$  blue. Plagioclase ( $An8^*$ )<sup>1</sup> is generally sausuritized. Chlorite exhibits anomalous Berlin blue interference colors, light to dark green pleochroism and is length fast. Epidote is colorless to light green. Accessory minerals are sphene and magnetite. Analysis 1 Appendix II is the only available analysis for the metabasalts.

#### Metatuffs

Metatuffs are exposed along a thin belt on the south limb of the Opawica River Anticline in La Ronde Township (Plate 2). Glacial drift covers much of the area and

---

<sup>1</sup>Plagioclase determinations marked by \* were made on sections perpendicular to X, and those marked by + were made in oils using Tsuboi's method.

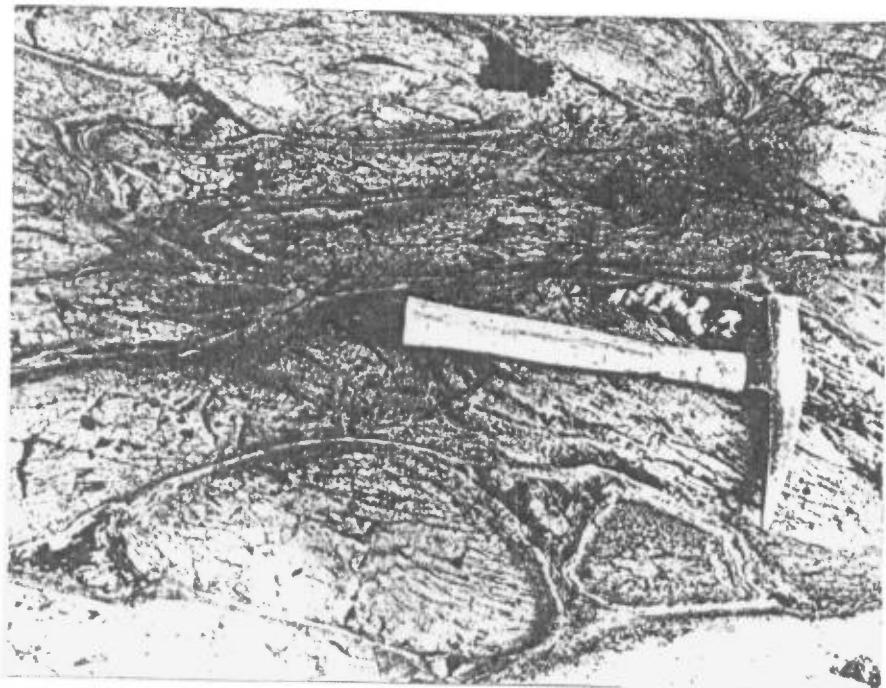

Figure 2. Outcrop of pillow basalt just north of Tush Lake. Geologic hammer is shown for scale. Stratigraphic tops are to the top of the photograph.

exposures are scarce. The best exposures are along bulldozed logging roads. The metatuffs can be subdivided into two principal rock units: basaltic metatuffs, and felsic metatuffs.

The metatuffs are generally well bedded and graded bedding in the felsic units provide excellent stratigraphic top determinations. Locally, the metatuffs are intensely deformed, exhibiting transposed primary layering (Figure 3) and crenulation cleavage (Figure 4). Because of their relative incompetency, it is likely that these units absorbed much of the regional orogenic strain.

The dominant rock type is a fine-grained, buff colored felsic tuff. Quartz and plagioclase (An9\*) comprise more than 75% of the rock. Subangular to subrounded quartz gains (up to 4 mm in diameter) and sericitized plagioclase (up to 3 mm) are present as megacrysts. Sericite or paragonite is the only other major constituent of this rock type. Pyrite was the only accessory mineral identified. The basaltic metatuffs are similar to those previously discussed.

#### Opawica River Complex

The Opawica River Complex is a metastratiform igneous intrusion. It bears striking similarities to other stratiform complexes in the region especially the Dore Lake Complex (Chibougamau) and the Bell River Complex (Matagami). The Opawica River Complex consists of a sequence of gabbroic anorthosite, anorthositic gabbro, gabbro, ferropyroxenite,

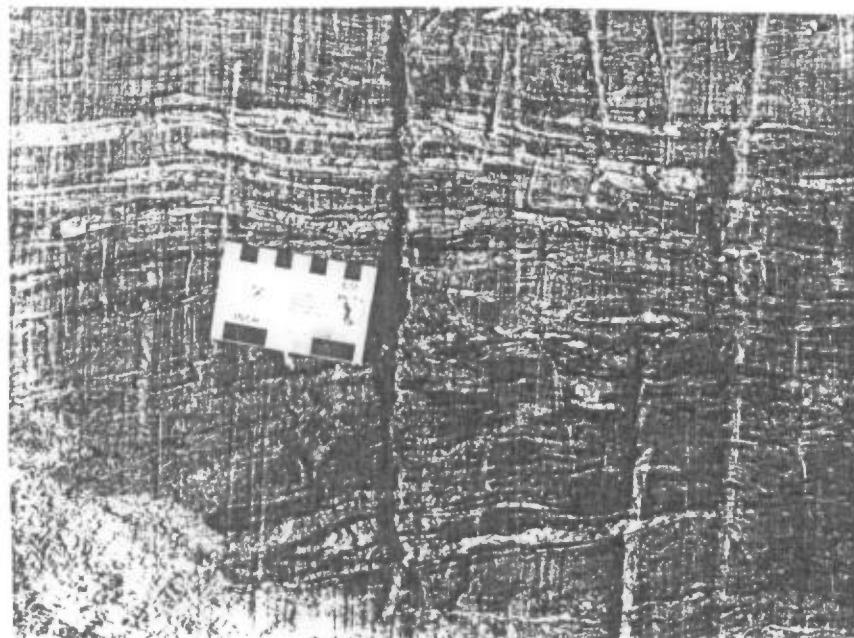

Figure 3. An outcrop of basaltic metatuff exhibiting transposed bedding. Vertical features are glacial grooves and striae. Photograph taken along logging road south of Tush Lake. Three inch rule is shown for scale.

and diabase that have been variably metamorphosed. The complex appears to have an overall sill-like morphology, however, it is locally discordant to the host rock volcanics. The volcanic sequence has been affected by deformational and thermal affects associated with the Kenoran Orogeny. The rocks of the complex exhibit mineral assemblages characteristic of the greenschist facies.

#### Opawica River Pluton

The Opawica River Pluton intrudes metabasalts and the Opawica River Complex. It is exposed in the axial zone of the Opawica River Anticline and is well exposed along the shores of the Opawica River and Lake Lessard. The most conspicuous megascopic structural feature is a foliation reflecting the preferred planar alignment of biotite and muscovite. This penetrative tectonic surface is generally subparallel to the trend of the Opawica River Anticline (Plates 1 and 2).

The rock is a grey color and can be classified as a biotite trondhjemite according to Williams *et al.* (1954). The predominant minerals are plagioclase, quartz, biotite, epidote, and muscovite. Plagioclase is typically zoned from An 27\* in the core to An 18\* in the rims. Chlorite is a common alteration feature of biotite. Muscovite is interstitial. Epidote is colorless and exhibits characteristic optical properties. The accessory minerals are sphene and chlorite. Analyses 35 and 36 in Appendix II are chemical analyses.

La Ronde Lake Pluton

The La Ronde Lake Pluton is an undeformed post-kinematic granitic pluton that intrudes metabasalts and the Opawica River Complex in the north central portion of the study area. It is concentrically zoned from a hornblende monzonite border to a porphyritic quartz monzonite core. A zone of brecciation is locally developed along the contact with the Opawica River Complex in Guercheville Township (Plate 1). The pluton's contacts are discordant to structural trends of the other rock units. Locally, a foliation defined by planar preferred orientation of hornblende is developed subparallel to the contacts. Presumably this fabric element developed during emplacement of the pluton. No contact metamorphic aureole appears to be associated with the pluton. The above mentioned descriptions are characteristic of plutons of the transition zone between the epizone and the mesozone of Buddington (1955).

Rocks of the La Ronde Lake Pluton (Analyses 38-54, Appendix II) are various shades of pink. In general the pluton is homogeneous with the only major mineralogical variation being a decrease in quartz abundance from the core to rim. Perthite and plagioclase are the most abundant minerals throughout the pluton, with the ratio of the two feldspars being approximately 1:1. Plagioclase (An 23\*) is zoned but the cores are too saussuritized and sericitized to determine their composition. Perthite is commonly interstitial, but locally forms phenocrysts (15 by 8 mm) in the core of the

pluton. Quartz is always interstitial. Hornblende ( $z \wedge c = 22^\circ$ ) typically comprises less than 20% by volume of the pluton. It has a pleochroic formula  $x =$  straw yellow,  $y =$  olive green, and  $z =$  blue green. Biotite occurs as reaction rims around hornblende. Chlorite is locally observed as an alteration product of biotite and hornblende. Accessory minerals are epidote, sphene, zircon, and apatite.

Experimental results on the system  $\text{NaAlSiO}_8 - \text{KAlSiO}_8 - \text{SiO}_2 - \text{H}_2\text{O}$  (Bowen & Tuttle, 1950, Luth et al., 1964, and Stiener et al., 1975) have led to a better understanding of granitic rocks. By plotting normative quartz, albite, and orthoclase, it is possible to compare granitic rocks containing more than 80% of these normative components to experimental results. The plot of the normative components for the La Ronde Lake Pluton (Figure 5) reveals a cluster near the 10Kb minimum of Luth et al. (1964). Such liquid compositions could be generated by fractional melting of quartzo-feldspathic material at depths of 35 kilometers or so.

#### Other Granitic Rocks

Two other granitic bodies are exposed in the northwest quarter of La Ronde Township. The relative areas of these two distinct rock types cannot be determined because the contacts are masked by glacial drift. A biotite granodiorite is exposed in the central portion of the northwest quarter of La Ronde Township and consists of biotite, zoned

plagioclase (An 28 core, An 20 rim \*), quartz, perthite, muscovite, and epidote. Accessory minerals are apatite, sphene, and zircon. Hornblende granodiorite is the other rock type. In hand specimen this rock is medium grained and has a salt and pepper appearance. Mineralogically it consists of partially saussuritized plagioclase (An 30\*), quartz, hornblende ( $Z/A_c = 24^\circ$ ) with a pleochroic formula  $x =$  straw yellow,  $y =$  blue green, and  $z =$  olive green, biotite, epidote, and chlorite. The accessory minerals are apatite, magnetite, and muscovite.

#### Structure

Pillow structures, scoriaceous flow tops, graded bedding, and the stratigraphy of the Opawica River Complex are the top and bottom criteria used to resolve the structure. In the northern portion of the study area stratigraphic tops face north while in the metatuffs to the south stratigraphic tops face south. The resulting structure is an anticline (Opawica River Anticline) with the Opawica River Pluton exposed in the axial zone. Observed dips are nearly vertical with the shallowest dips being approximately  $70^\circ$ . These steep dips indicate that the anticline is isoclinal.  $S_2$  crenulation cleavages were observed locally in the metatuffs, but with less than six readings it is impossible to resolve this fabric element.

Three faults having the same general trend (N2)E-N30E) were mapped.

## CHAPTER III

### OPAWICA RIVER COMPLEX

The Opawica River Complex has been divided into two zones (Plates 1 and 2); an Anorthosite Zone, stratigraphically the lowest exposed portion of the complex, and a Gabbro-Ferropyroxenite Zone which encompasses the upper portion of the complex. The Anorthosite Zone has a maximum outcrop width of 12,000 feet (3650 meters). Lithologies within the Anorthosite Zone (Analyses 2-29; Appendix II) are (in decreasing abundance): gabbroic anorthosite, anorthositic gabbro, and gabbro. The Gabbro-Ferropyroxenite Zone (Analyses 30-34; Appendix II) consisting of gabbro, ferropyroxenite, and diabase has a maximum outcrop width of 3000 feet (900 meters). Since the rocks are nearly vertical, outcrop width is nearly the same as the true thickness.

#### Textural Relations and Layering

#### Textural Relations

With the exception of the diabases within the Gabbro-Ferropyroxenite Zone, rocks of the Opawica River Complex are cumulates (usage of Wager & Brown, 1967). In other stratiform complexes (Bushveld Complex, Stillwater Complex, and Skaergaard Intrusion) the accumulated crystals are either plagioclase, orthopyroxene, olivine, Fe-Ti oxides, chromite,

and apatite, but in the Opawica River Complex plagioclase and clinopyroxene are the only cumulate phases. Grain size varies from 1 mm (Figure 6) to over 15 cm (Figure 7). Another cumulus texture that is prevalent in the Anorthosite Zone is a hiatal texture characterized by two distinct sizes in the plagioclase crystals (Figure 8). This texture could result from having two generations of plagioclase crystals. Primary pyroxene replaced by metamorphic amphibole is generally intercumulus of the plagioclase and forms large blastopoikilitic<sup>2</sup> crystals. Fe-Ti oxides form intercumulus grains. Cameron (1969) suggests that post-cumulus changes in cumulus minerals could make minerals appear "intercumulus." It is possible that post-cumulus changes affected the oxides in the Opawica River Complex in this manner, but there is no textural evidence to support this theory. The diabases have an ophitic texture and occasionally contain megacrysts of plagioclase (Figure 9).

#### Layering

Three types of layering in plutonic igneous rocks defined by Wager and Deer (1939) were rhythmic, cryptic, and igneous lamination. Hess (1960) defined two other types of layering, phase layering and inch-scale layering, based on observations of the Stillwater Complex, Montana.

---

<sup>2</sup>The suffix blasto- refers to igneous textures that have survived metamorphism, but the original igneous mineral has been replaced by a metamorphic mineral.

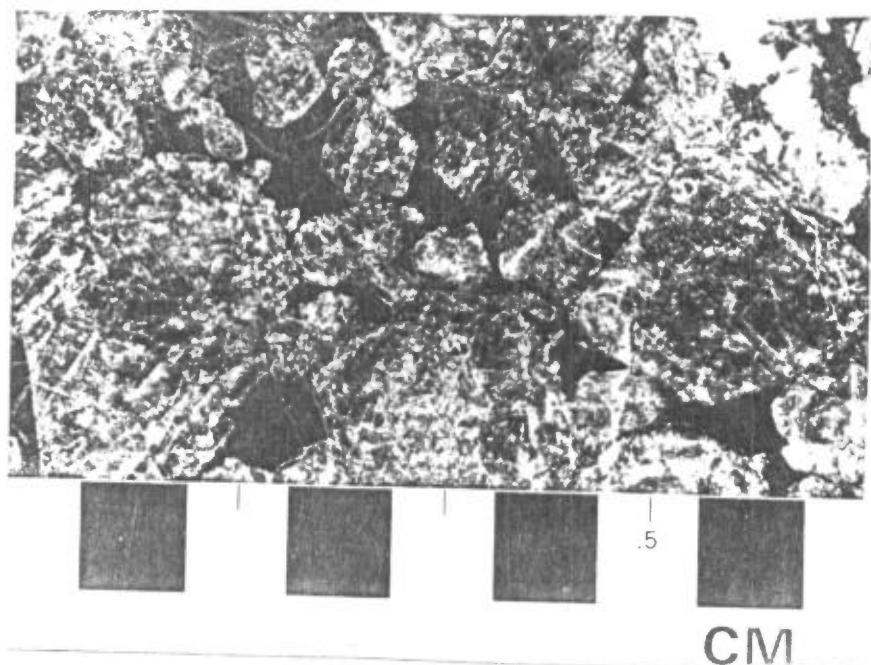

Figure 6. Photograph of a polished slab of a gabbroic anorthosite sample 73BM164 displaying cumulus texture. The light phase is plagioclase and the dark intercumulus phase is actinolite replacing primary pyroxene.

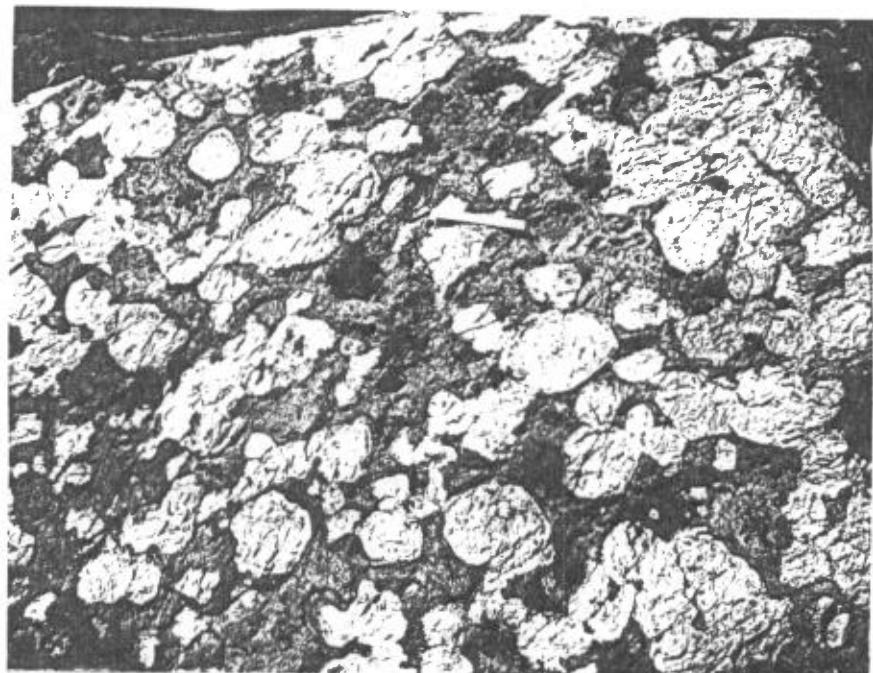

Figure 7. Photograph of an outcrop of coarse grained anorthositic gabbro exhibiting cumulus texture. The light phase is cumulus plagioclase and the dark phase is intercumulus actinolite replacing primary pyroxene. Photograph taken along a logging road in La Ronde Township. Six inch rule is shown for scale.

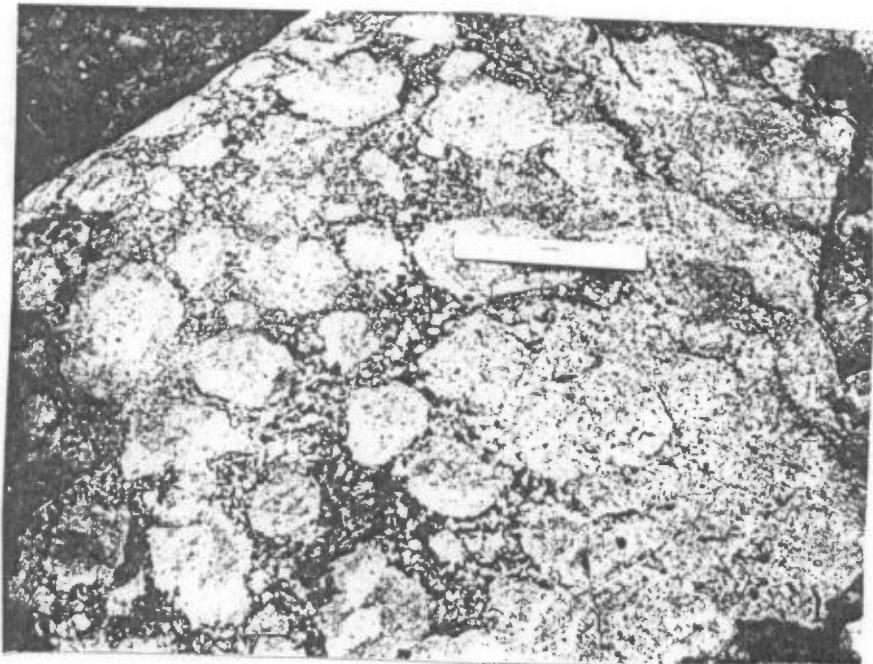

Figure 8. Photograph of an outcrop displaying hoidal texture in gabbroic anorthosite. Note the two distinct sizes of plagioclase (light). Photograph taken along a logging road in La Ronde Township. Six inch rule is shown for scale.

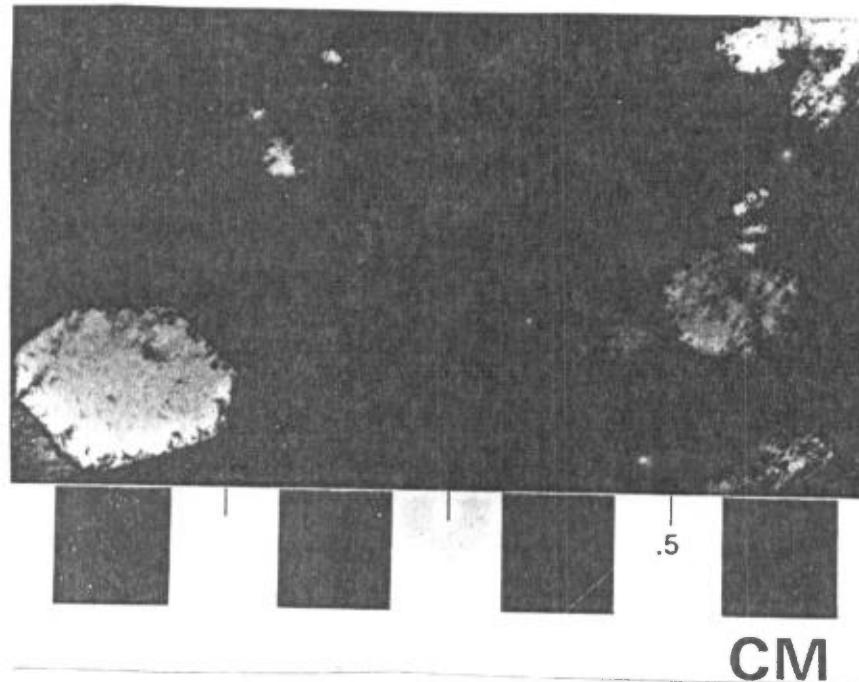

Figure 9. Photograph of a polished slab of sample 73BM174 displaying megacrysts of plagioclase in a diabase from the Gabbro-Ferropyroxenite Zone.

Within the Opawica River Complex rhythmic, cryptic, and inch-scale layering were observed. On the outcrop scale, layering results from either a difference in the mafic to felsic ratio (Figure 10), and/or a difference in grain size (Figures 11 and 12). Slightly irregular layering (Figure 13) and possible igneous cross-bedding (Figure 14) were also observed. Cryptic layering will be discussed in another section.

#### Anorthosite Zone

Rocks of the Anorthosite Zone consist of gabbroic anorthosite, gabbro and anorthositic gabbro. Gabbroic anorthosite is the most common lithology. The rocks are coarse grained with the grain size varying from 1 mm to 15 cm. Cumulus textures are common and layering is well developed.

Plagioclase (An 84-76+) is generally unaltered and is the dominant cumulus phase. Metamorphic amphiboles have replaced primary intercumulus pyroxene, but remnant pyroxenes are locally preserved.

#### Mineralogy

The essential minerals are plagioclase (50-90%), actinolite (5-45%), clinozoisite (0-10%), chlorite (0-5%), magnetite, and ilmenite (0-25%). Minor constituents are augite, sphene, and sericite (Table 2). The sericite in the rocks may be paragonite since the rocks are low in  $K_2O$  (Table 3).

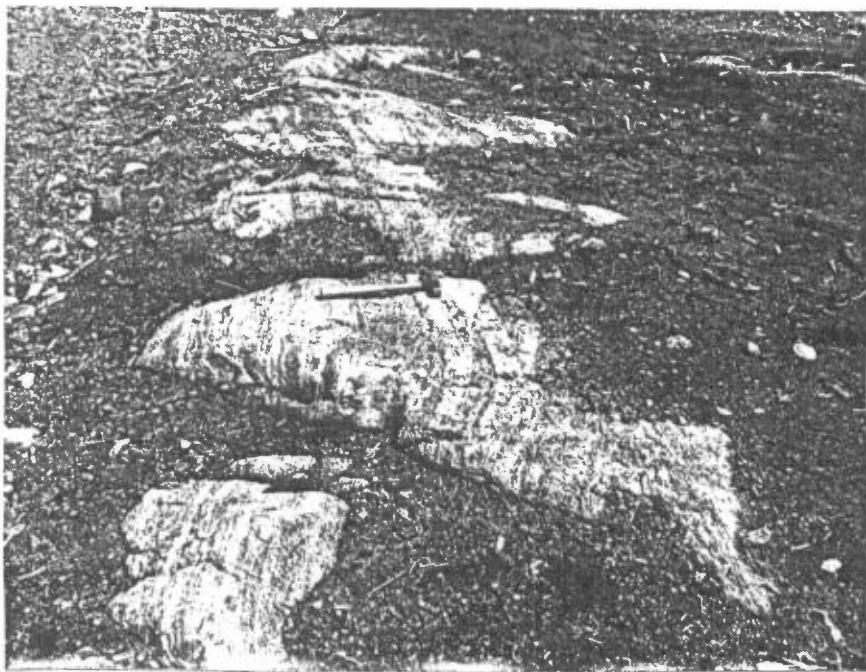

Figure 10. Inch-scale layering in gabbro of the Anorthosite Zone. Outcrop is along a logging road in La Ronde Township. The geologic hammer is shown for scale. Layering is the result of a difference in mafic to felsic ratio.

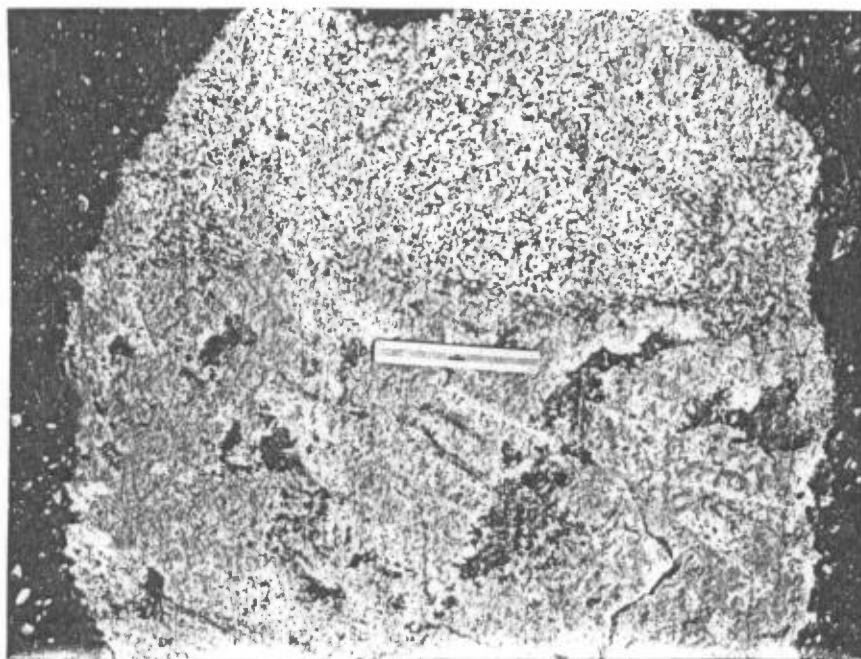

Figure 11. Layering in the Anorthosite Zone resulting from a difference in mafic to felsic ratio and grain size difference. Photograph taken along a logging road in La Ronde Township. Six inch rule is shown for scale. A well developed cumulus texture can be seen in the gabbroic anorthosite in the upper portion of the photograph. The lower portion of the photograph is an anorthosite. The light colored mineral is plagioclase which forms the cumulus grains. The dark mineral is actinolite which replaces primary intercumulus pyroxene.

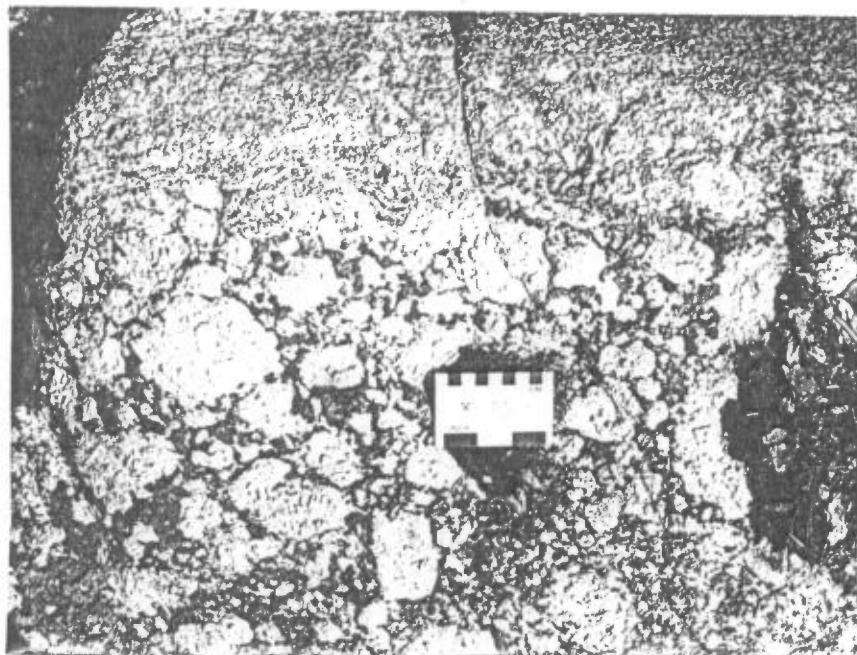

Figure 12. Layering in the Anorthosite Zone resulting from a difference in grain size and mafic to felsic ratio. Photograph taken along a logging road in La Ronde Township. Three-inch rule is shown for scale. A hiatal texture is developed in the lower portion of the picture. The dark mineral is actinolite that has replaced primary intercumulus pyroxene. The light mineral is cumulus plagioclase.

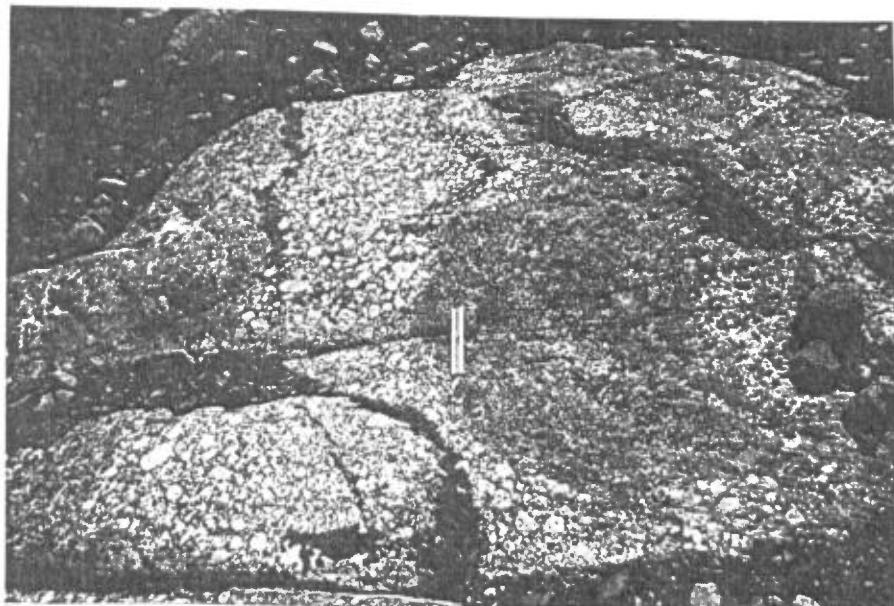

Figure 13. Irregular layering in the Anorthosite Zone resulting from a difference in mafic to felsic ratio. Photograph taken along a logging road in La Ronde Township. Six-inch rule is shown for scale. The large light colored mineral is plagioclase. The dark mineral is actinolite that replaced primary intercumulus pyroxene.

Figure 14. Possible igneous cross-bedding in the Anorthosite Zone. Photograph taken along a logging road in La Ronde Township. Geologic hammer in the upper part of the outcrop is shown for scale. The rocks in the upper portion dip from top to bottom while the rocks in the lower portion dip from left to right.

Polysynthetically twined plagioclase occurs as euhedral cumulus grains varying in size from 1 mm -15 cm. The contacts between plagioclase and blasto-intercumulus actinolite commonly have a border of clinozoisite (Figure 15). Clinozoisite is also present along cracks and fractures in plagioclase and, locally, as pseudomorphs of primary plagioclase.

Metamorphic actinolite ( $z \wedge c = 11^\circ - 20^\circ$ , Analyses 1, 2, 3, Table 4) has a pleochroic formula  $x = \text{straw yellow}$ ,  $y = \text{green}$ , and  $z = \text{blue green}$ . Granoblastic and blasto-poikilitic varieties (Figure 16 A and B) are always intercumulus to plagioclase.

Remnant primary clinopyroxene (Analyses 4 and 5, Table 4) were identified. All observed clinopyroxenes have exsolution lamellae of orthopyroxene (Figure 17) and are altered to actinolite.

Pale green chlorite is present in most thin sections studied. It is pleochroic from colorless to pale green and is length fast. Chlorite is commonly found near or along grain boundaries with plagioclase (Figure 18). This is probably due to the availability of Al from plagioclase during metamorphism, however, chlorite can pseudomorph pyroxene and be intercumulus to plagioclase.

Fe-Ti oxides are found as "intercumulus" grains throughout the Anorthosite Zone. They do not, however, constitute more than 25% by volume (Table 2). Ilmenite is the only oxide observed in the lower half of the zone, while

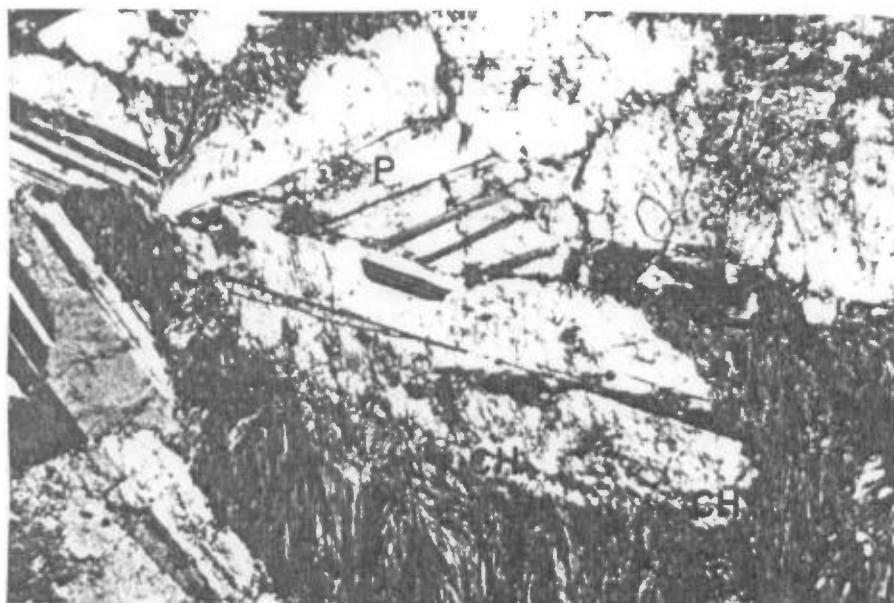

Figure 18. Photomicrograph of gabbroic anorthosite (74AM5). Blasto-intercumulus actinolite (A) with a border of chlorite (CH) at grain boundaries with cumulus plagioclase (P). Crossed polars, width of field 6.5 mm.

magnetite and ilmenite occur in the upper half. In reflected light, ilmenite is grey brown in color and strongly anisotropic while magnetite is grey in color and isotropic. Magnetite grains generally contain exsolution lamellae of ilmenite (Figure 19). Ilmenite also occurs as discrete grains. In some instances, magnetite is replaced by epidote and chlorite, but lamellae of ilmenite may still be identifiable (Figure 20).

Sphene and sericite are accessory minerals. Sericite is found associated with plagioclase. In some cases, the sericite may be paragonite since the rocks have very low concentrations of  $K_2O$ . Sphene commonly occurs as a fine dust in actinolite, and probably formed from the release of  $T_i$  in the reaction titanaugite +  $H_2O$  = actinolite + sphene. It is also found as a replacement product of ilmenite.

#### Gabbro-Ferropyroxenite Zone

The Gabbro-Ferropyroxenite Zone (Plate 2) is exposed only in La Ronde Township. Metagabbro, metaferropyroxenite, and metadiabase are the major rock types that constitute the zone. The rocks are generally finer grained than those of the Anorthosite Zone. The metaferropyroxenites resemble the enclosing metabasalts, however their lack of volcanic features and the abundance of finely disseminated magnetite distinguished them from the metabasalts. The gabbros are dark green and exhibit well developed cumulus textures (Figure 21). The metadiabases have a subophitic texture

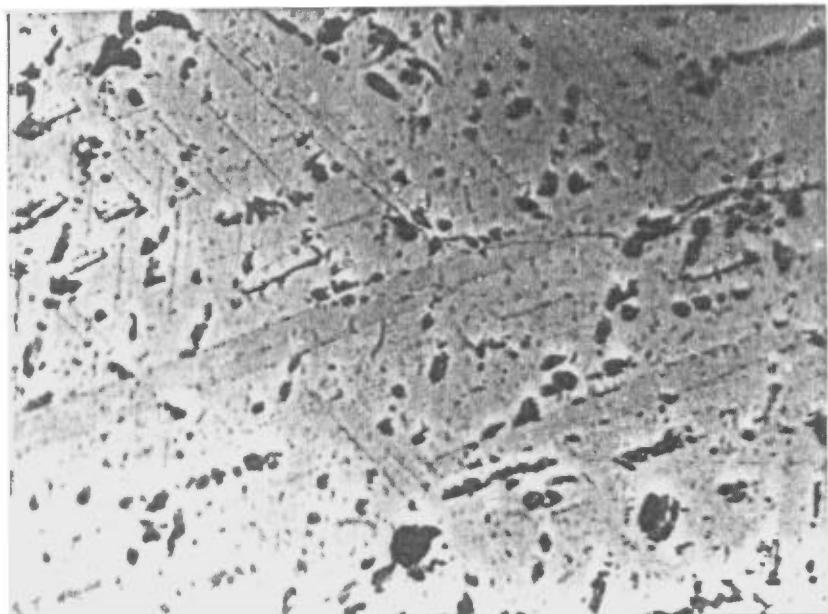

Figure 19. Reflected light photomicrograph of a gabbro (74RA55). Magnetite (M) grain with exsolved lamellae of ilmenite (I). The texture resulted from the oxidation of magnetite.

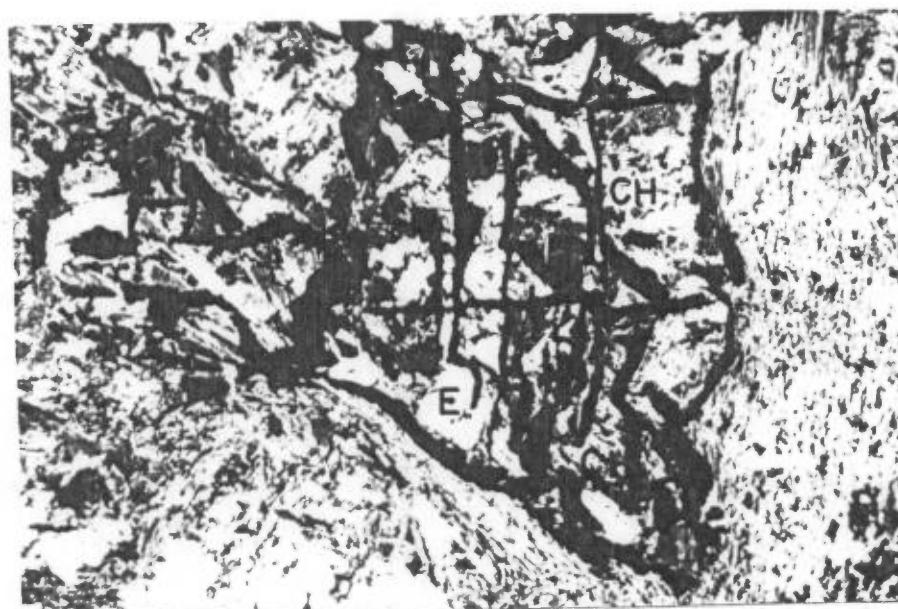

Figure 20. Photomicrograph of anorthositic gabbro (74AM195). Shown is an original grain of titaniferous magnetite that has been replaced by epidote (E), and chlorite (CH) leaving only the ilmenite (I) lamellae. Plain light, width of field 6.5 mm.

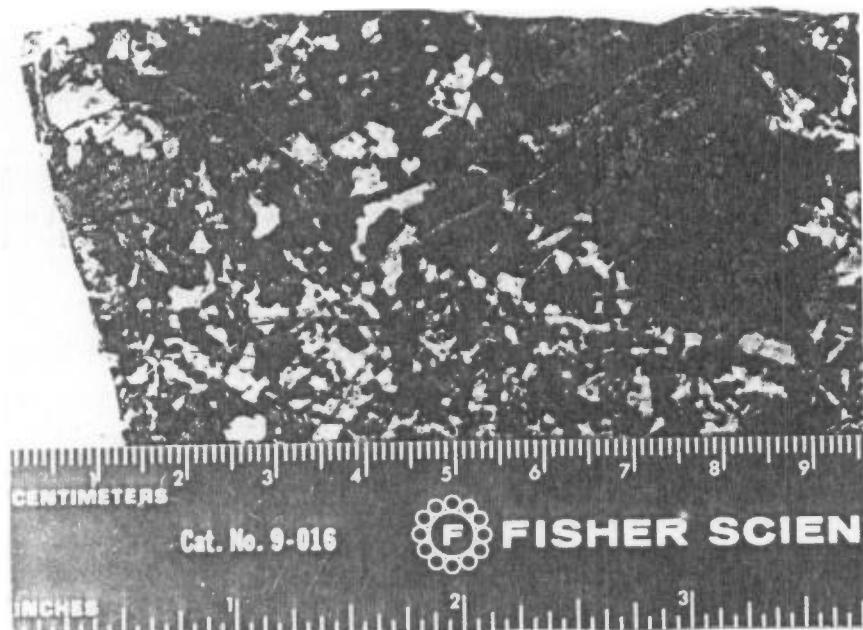

Figure 21. Polished slab of gabbro (74RA144) displaying cumulus texture. Note the intercumulus nature of the plagioclase (light) and the cumulus actinolite and pyroxene (dark).

and megacrysts of plagioclase (Figure 9) are common. Metamorphism appears to have produced more extensive recrystallization in rocks within the Gabbro-Ferropyroxenite Zone than in those of the Anorthosite Zone.

#### Mineralogy

The principal minerals of the Gabbro-Ferropyroxenite Zone are plagioclase, actinolite, clinozoisite-epidote, chlorite, and Fe-Ti oxides. Minor constituents are ferrohastingsite, clinopyroxene, and quartz.

Polysynthetically twinned plagioclase (An 69+) occurs in the gabbros both as cumulus and intercumulus grains. The plagioclase in the metaferropyroxenites and diabases is generally saussuritized.

Metamorphic actinolite and ferroactinolite are present as pseudomorphs of primary clinopyroxene. These amphiboles vary in color from green to pale green to yellow (Analyses 1, 2, 3, Table 5).

Ferrohastingsite occurs associated with lamellae of ilmenite (Figure 22). This amphibole has a 2V of 10-40° and is strongly pleochroic: x = straw yellow, y = dark green, z = dark bluish green. It is thought that ferrohastingsite formed from the reaction: plagioclase + magnetite + augite + water = ferrohastingsite. Baskin (1975) reports ferrohastingsite from the Dore Lake Complex and writes a similar reaction: plagioclase + magnetite + ferroaugite = ferrohastingsite. Electron microprobe analysis of

See Appendix for analytical procedures.

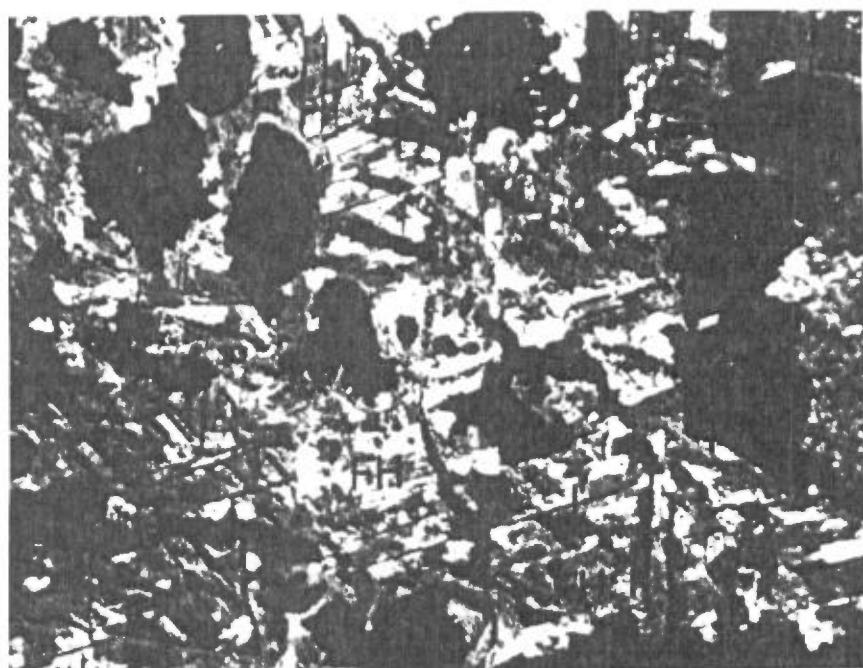

Figure 22. Photomicrograph of gabbro (74RA143) showing ferrohastingsite (FH) replacing magnetite, but the lamellae of ilmenite still remains. Plain light, width of field 6.5 mm.

ferrohastingsite (Analysis 4, Table 5) reveals an appreciable amount of  $V_2O_3$ . Magnetites from the Opawica River Complex contain considerable amounts of vanadium (Table 8) while pyroxenes contain no vanadium (Table 5). The vanadium content of the ferrohastingsite and its association with lamellae of ilmenite suggests that magnetite supplied much of the needed iron to form ferrohastingsite.

Chlorite is more strongly colored than chlorite from the Anorthosite Zone and varies from pale green to green. It has anomalous Berlin blue interference colors and is length fast.

Fe-Ti oxides occur as "intercumulus" grains with similar textural relations as described in the Anorthosite Zone. Ilmenite is grey brown and strongly anisotropic while magnetite is isotropic. Sphene occurs as an alteration of ilmenite (Figure 23).

Remnant primary clinopyroxene identified as augite was observed in one thin section. It occurs as cumulus grains that exhibit various stages of alteration to actinolite (Figure 24).

#### Cryptic Variations

Hess (1960) describes cryptic layering as ". . . the inconspicuous, and for the most part gradual change in composition of mineral phases upward in the intrusive." Plagioclase, clinopyroxene, magnetite, and ilmenite will be used to illustrate cryptic variations within the Opawica River Complex.

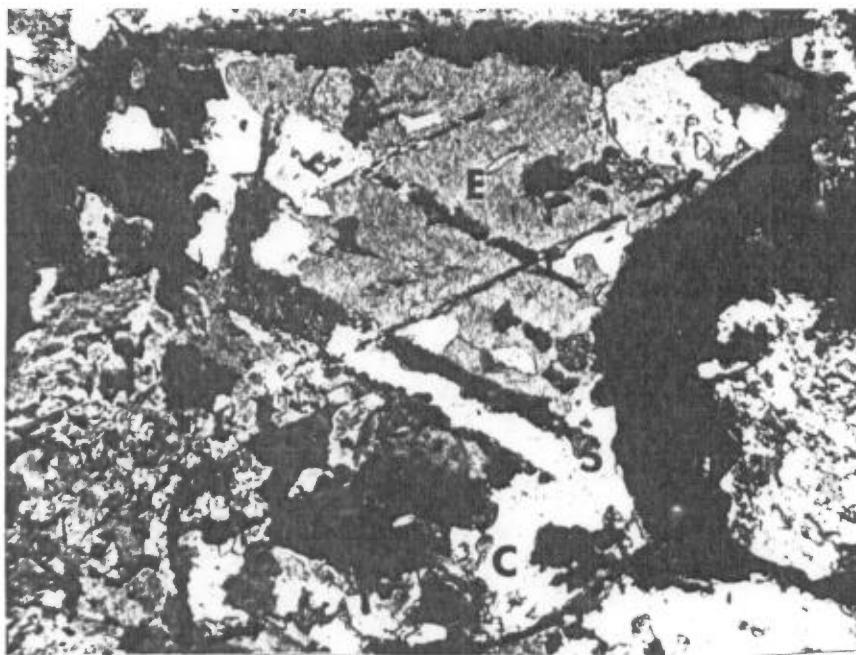

Figure 23. Photomicrograph of a gabbro (74RA144). Sphene (S) has partially replaced lamellae of ilmenite (I), white carbonate (C), epidote (E), and ferrohas-tingsite (FH) have replaced magnetite. Crossed polars, width of field 3 mm.

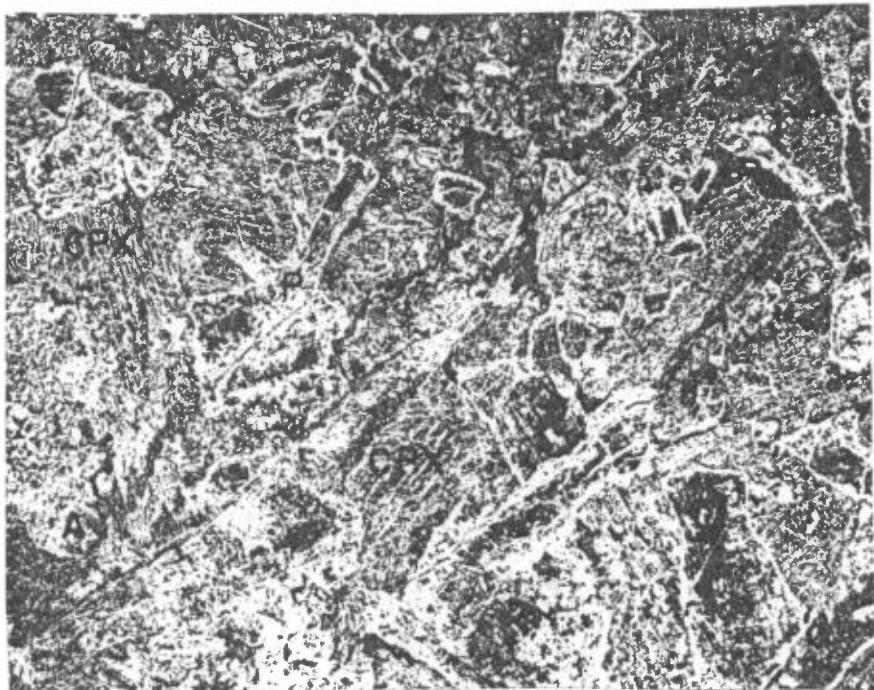

Figure 24. Negative representation of a thin section of 74RAL44 a gabbro. Cumulus primary clinopyroxene (CPX) is partially replaced by actinolite (A). Plagioclase (P) is intercumulus.

### Plagioclase

Plagioclase persists as a cumulus phase throughout the Anorthosite Zone and a portion of the Gabbro-Ferropyroxenite Zone. While plagioclase (An 84-69+) at the top is more sodic than at the bottom, there is no clear trend. There does, however, appear that fluctuations in An content occurs with an increase in structural height (Figure 25). Hess (1960) attributes similar fluctuations in An content of plagioclase in the Stillwater Complex, Montana, to varied rates of crystal accumulation. On the other hand, Wadsworth (1961) attributes fluctuations on anorthite content to the replenishment of the magma chamber by parental magma. It is proposed that Hess's hypothesis best explains this phenomenon in the Opawica River Complex.

### Clinopyroxene

Remnant primary intercumulus and cumulus clinopyroxene containing exsolved lamellae of orthopyroxene was identified from the Opawica River Complex. Pyroxenes from the Opawica River Complex (Tables 4 and 5) exhibit a slight iron enrichment trend (Figure 26), however, their most striking compositional variation is in calcium content. The trend is somewhat misleading because the exsolved orthopyroxene was not analyzed.

### Fe-Ti Oxides

Three samples containing coexisting magnetite and ilmenite were chosen for analysis in order to illustrate any

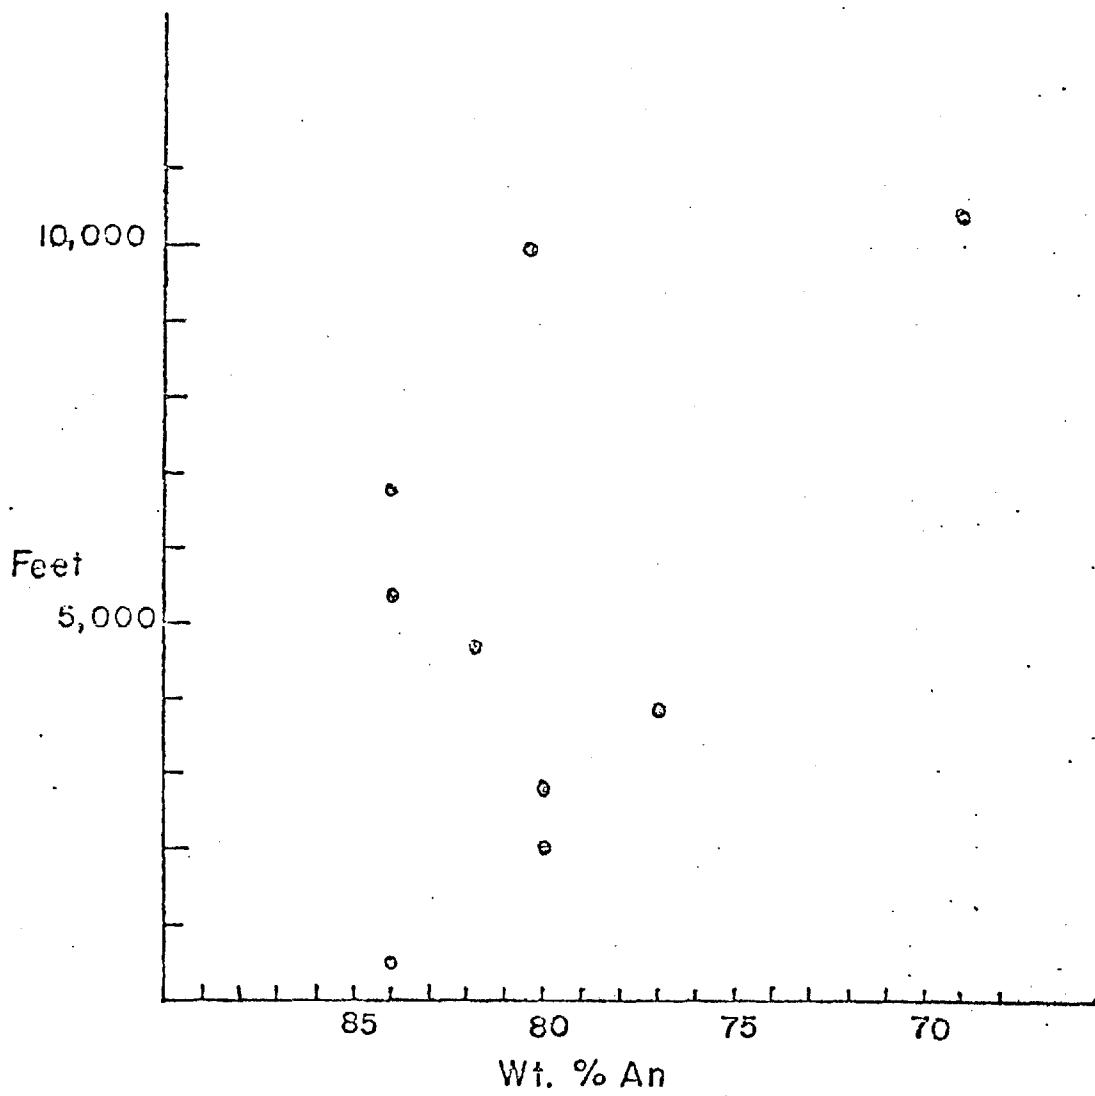

Figure 25. Anorthite content of plagioclase (determined optically) plotted against height above contact with the Opawica River Pluton.

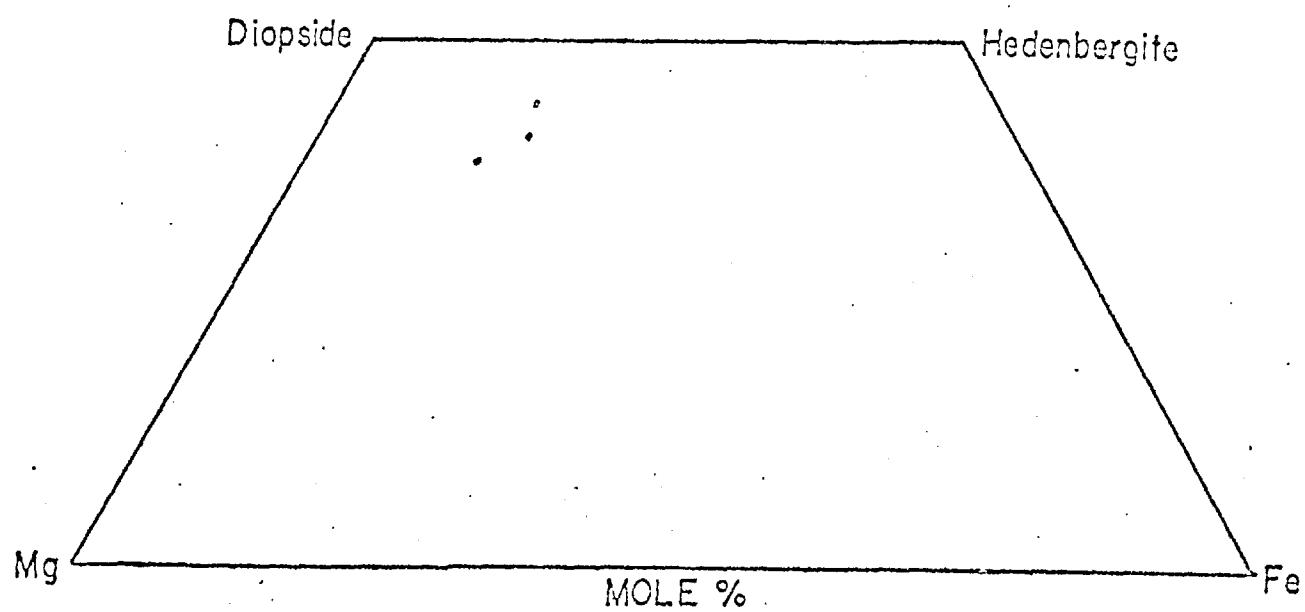

Figure 26. Plot of pyroxenes from the Opawica River Complex.

chemical variation exhibited by the minerals. The analyzed magnetite (Table 8) contained exolved ilmenite which were not included in the analysis.

In Figures 27 and 28 major and minor oxides are plotted against structural height above the level of intrusion of the Opawica River Pluton. Vanadium was discovered to have higher concentrations in the magnetites while the ilmenites had a higher concentration of manganese. A similar relationship exists between the magnetites and ilmenites of the Dore Lake Complex (Caty, 1970).

#### Geochemistry

One of the purposes of this study was to define the chemical characteristics of the Opawica River Complex. The preservation of original igneous structures and textures (Figures 6, 7, 8, 10, 11, 12, 13, and 14) and the similarity between original minerals and their metamorphic equivalents indicate that metamorphism was essentially isochemical; thus the bulk chemistry of the rocks was unaffected (Table 3). Since cumulate rocks do not represent liquid compositions, only gabbroic rocks were chosen to define the complex chemically.

Several chemical series are recognized in basaltic igneous rocks among these alkaline, calc-alkaline, and tholeiitic. The  $(\text{Na}_2\text{O} + \text{K}_2\text{O})/\text{SiO}_2$  variation diagram of MacDonald and Katsura (1964) and Kuno (1965) can be used to distinguish the alkaline series from the calc-alkaline and

tholeiitic series. An AFM diagram can be used to distinguish the tholeiitic series from the calc-alkaline series. The calc-alkaline trend is marked by an alkali enrichment and lime impoverishment while the tholeiitic trend is marked by an iron enrichment as well as an alkali enrichment and lime impoverishment.

The gabbroic rocks of the Opawica River Complex have been plotted on the  $(\text{Na}_2\text{O} + \text{K}_2\text{O})/\text{SiO}_2$  variation diagram (Figure 29). Most of the analyzed rocks are tholeiitic according to MacDonald and Katsura (1964), but many plot in the high alumina basalt field of Kuno (1965). Oliveira (1963) has described similar chemical characteristics for basalts and gabbros from Chibougamau, and used the  $\text{SiO}_2-\text{Al}_2\text{O}_3-(\text{Na}_2\text{O} + \text{K}_2\text{O})$  diagram to resolve this discrepancy. Rocks from the Opawica River Complex are plotted on the  $\text{SiO}_2-\text{Al}_2\text{O}_3-(\text{Na}_2\text{O} + \text{K}_2\text{O})$  variation diagram (Figure 30) and all fall within the tholeiitic field.

An AFM diagram was used to distinguish the calc-alkaline series from the tholeiitic series (Figure 31). The chemical variations observed for the rocks of the Opawica River Complex exhibit an iron enrichment trend, but no alkali enrichment. The absence of an alkali enrichment trend like the one exhibited by the Skaergaard Intrusion (Figure 32) can be explained by the absence of granophyric differentiates in the Opawica River Complex. Even though there is no alkali enrichment, the differentiation trend exhibited by the rocks of the Opawica River Complex has tholeiitic affinities.

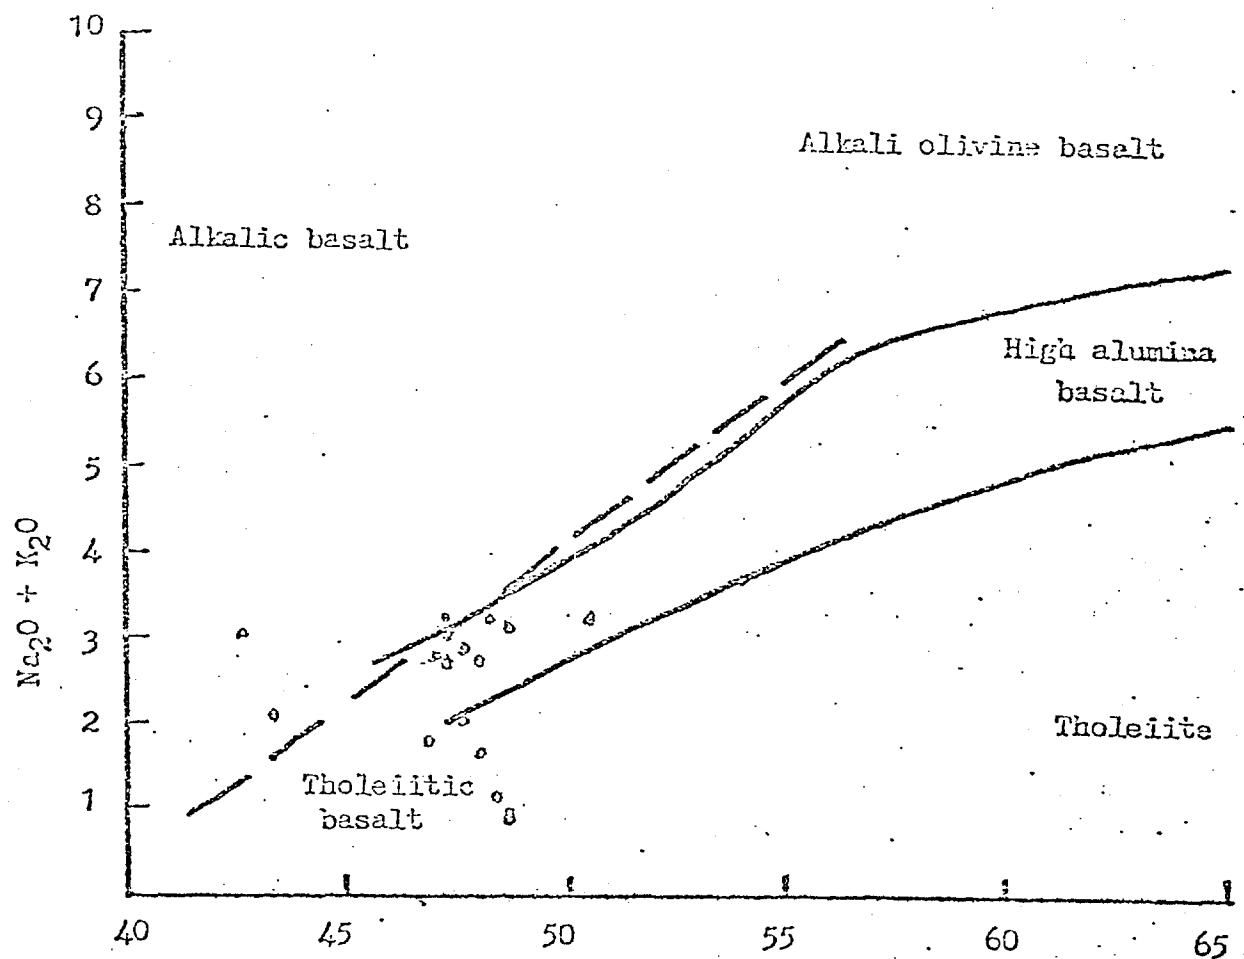

Figure 29.  $(\text{Na}_2\text{O} + \text{K}_2\text{O})/\text{SiO}_2$  plot for gabbroic rocks of the Opawica River Complex. (\*) after McDonald and Katsura, 1964), (— after Kuno, 1965).

Crystallization History and Evolution of the  
Opawica River Complex

In order to design a model for the crystallization history of the Opawica River Complex, it is necessary to list significant characteristics of well studied layered mafic intrusions. Most layered complexes have very similar stratigraphic sequences (Figure 33). The stratigraphy can be simplified into four major zones or their equivalents (Allard, 1973): (1) an ultramafic zone, (2) anorthosite zone, (3) layered zone or gabbro zone, and (4) granophyre zone. Although in the Opawica River Complex only two of the zones are exposed, it is postulated that a granophyre zone existed and possibly an ultramafic zone.

The original form of the Opawica River Complex is believed to be that of a tilted sheet-like body (Figure 34). It is necessary for the intrusion to be tilted in order to explain the present outcrop pattern (Plates 1 and 2). A single intrusive pulse filled the magma chamber, and crystallization proceeded in a closed system with the original magma having tholeiitic affinities. If the diabasic rocks of the complex represent a chilled border phase, then the megacrysts of plagioclase suggest that the original magma was charged with plagioclase crystals. Assuming a density of 2.7 for the magma (Hess, 1960; Wager & Brown, 1967), it is likely that the plagioclase crystals would have remained suspended until they reached a size that would enable them to sink according to Stokes' Law. The cumulate nature of

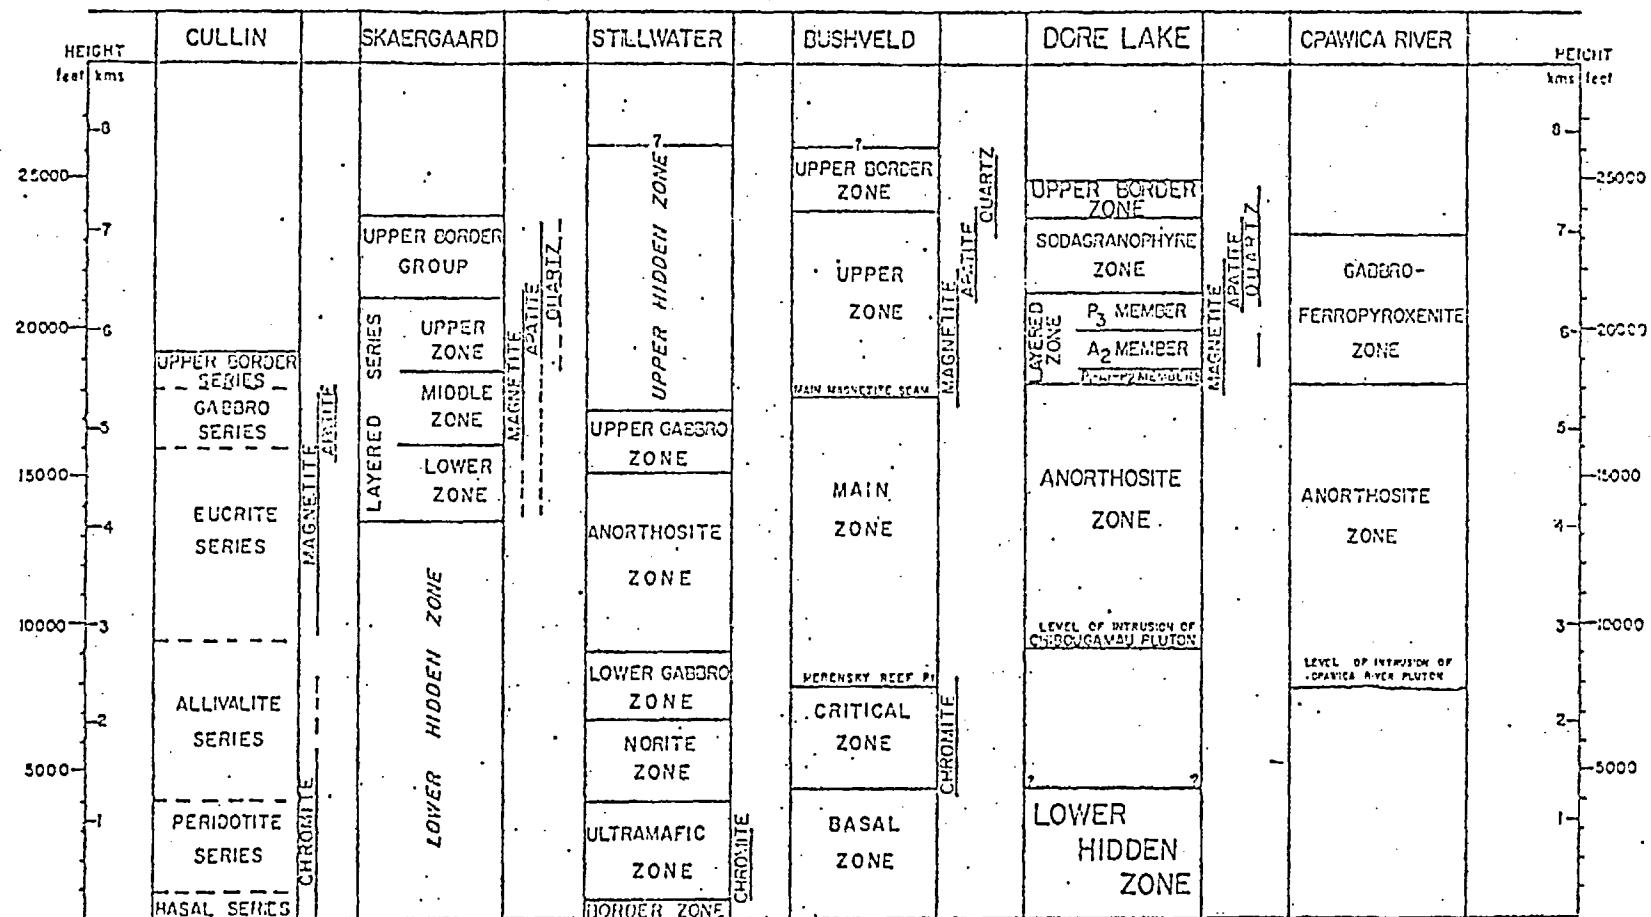

Figure 33. Comparison of the stratigraphy of the Opawica River Complex to other layered complexes. Modified from Allard, 1973.

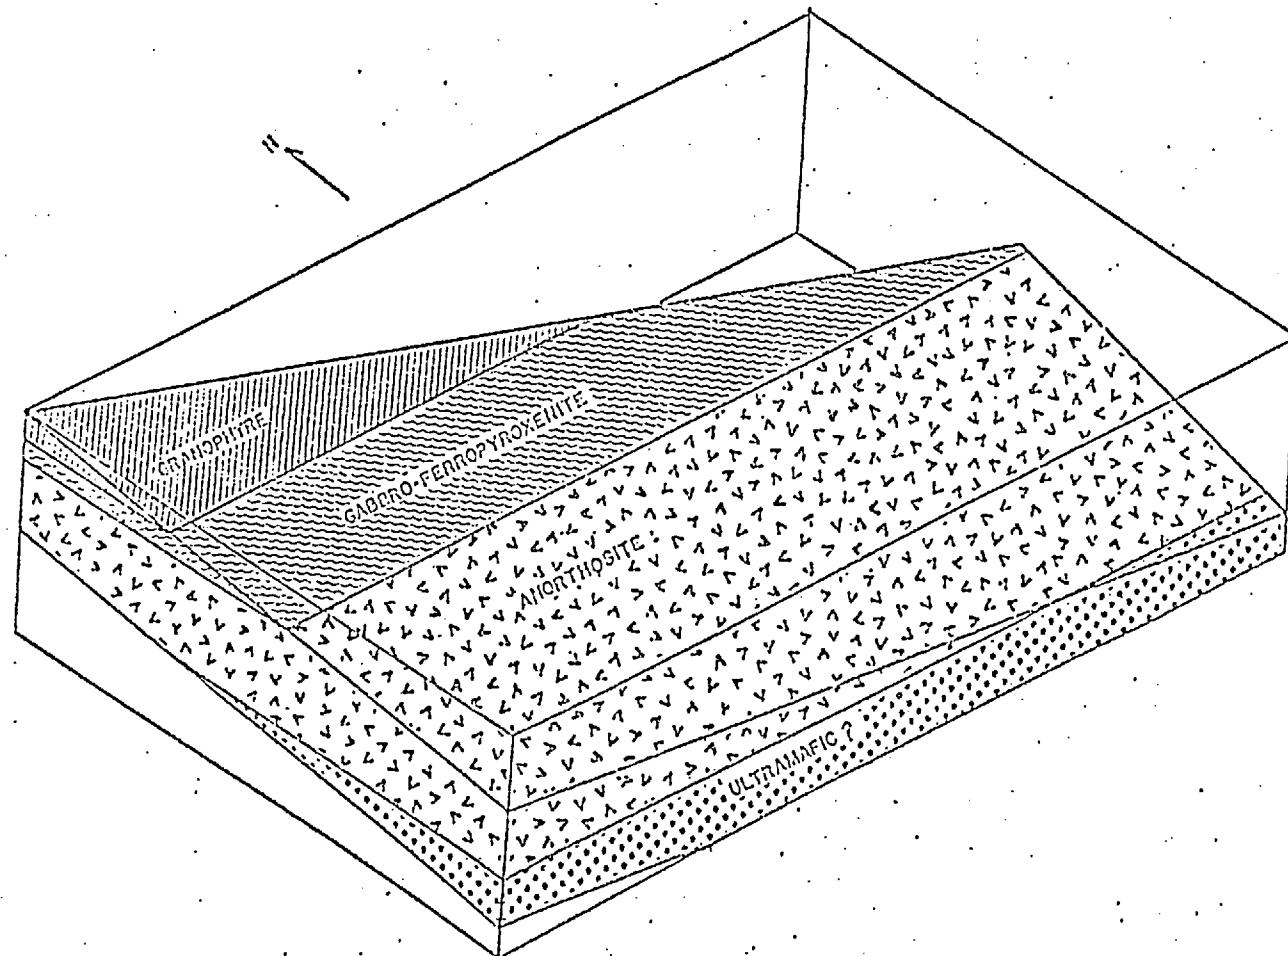

Figure 34. Sketch of the Opawica River Complex after crystallization. Sketch not drawn to scale.

the rocks and layering indicate that the complex formed by the accumulation of crystals on the floor of a magma chamber. The lack of a large layered zone suggests that convection currents of the type hypothesized for the Stillwater Complex (Hess, 1960) did not play an important role in the formation of the complex.

At the conclusion of crystallization, the complex is thought to have the stratigraphy seen in Figure 34 with the possible exception of the ultramafic zone. The existence of an ultramafic zone is necessary to explain the large volume of anorthositic rocks differentiating from a basaltic magma. However, if the original magma was that of a high alumina basalt having tholeiitic affinities, the existence of an extensive ultramafic zone would not be necessary. The complex was intruded by the Opawica River Pluton and folded into an east-west trending anticline (Figure 35). The granophyre zone was removed by erosion and the ultramafic zone if it does exist would be found below the Opawica River Pluton.

## CHAPTER IV

## METAMORPHISM

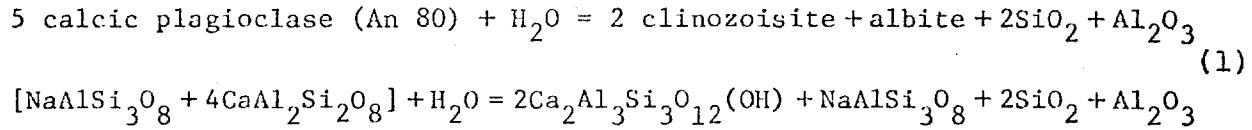

A single metamorphic event believed to be associated with the Kenoran Orogeny altered the rocks of the Opawica River Complex. Except for relict primary igneous minerals, typical greenschist mineral assemblages characterize the complex and related rocks. The most important primary igneous minerals of the complex were plagioclase, clino-pyroxene, magnetite, and ilmenite. The mineral assemblage albite + actinolite + clinzoisite + chlorite in the rocks of the study area indicate regional metamorphism of the quartz-albite-muscovite-chlorite subfacies of the greenschist facies.

Turner (1968) and Winkler (1967, 1974) stress the importance of the catalytic action of water during metamorphism, without which "the metamorphism of basalts to amphibolites or chlorite-epidote greenschists would have been impossible" (Winkler, 1974). Original intercumulus minerals evidently acted as a channel for water and other volatiles during metamorphism. As a result, original intercumulus pyroxene altered to amphibole; calcic plagioclase remained stable except along grain boundaries with amphibole where zoisite and albite became the stable assemblage, and cumulus pyroxene remained stable except along grain boundaries with plagioclase where actinolite became the stable assemblage.

Such conditions may indicate either insufficient quantities of water available for more complete alteration of cumulus phases or insufficient porosity-permeability to allow the passage of water to the entire rock.

### Plagioclase

Plagioclase is the most abundant cumulus mineral in the complex. Calcic plagioclase (An 84-69+) has for the most part survived metamorphism. As described above, where water was available in sufficient quantities calcic plagioclase altered to an aggregate of clinozoisite and/or epidote and albite. The following reaction describes the transformation:

502.9 cc

466.9 cc

Petrographic evidence indicates that the excess alumina reacts with augite to form chlorite, which when present is found at grain boundaries between plagioclase and actinolite (Figure 36).

### Pyroxene

Augite is the only original mafic silicate mineral identified from the Opawica River Complex. Originally, it was present throughout the complex as an intercumulus phase

and a cumulus phase in the Gabbro-Ferropyroxenite Zone.

Subsequently, augite was altered to actinolite and chlorite:

392.47 cc

406.13 cc

There is petrographic evidence that chlorite formed from the alteration of augite with the addition of alumina. The formation of chlorite can be described by the following reaction:

417.96 cc

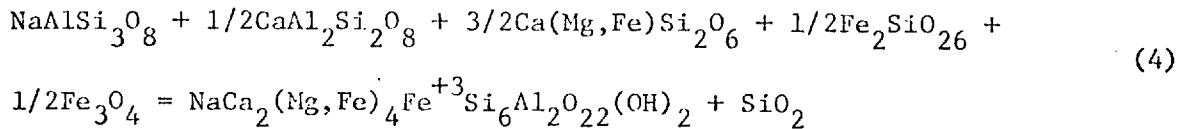

542.14 cc

The excess silica and lime produced by the above reaction is available for the formation of sphene from ilmenite (reaction 6).

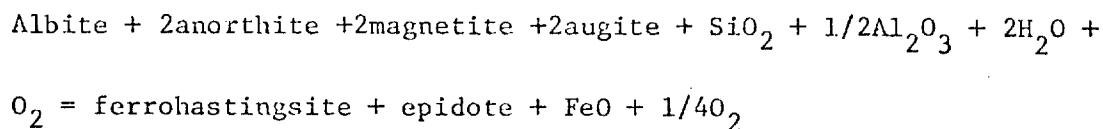

### Magnetite

In the Opawica River Complex magnetite is present only as an "intercumulus" phase. Petrographic and chemical evidence indicate that magnetite was an important reactant in the formation of ferrohastingsite and epitode. Ferrohastingsite evidently replaced magnetite leaving lamellae oriented parallel to the magnetite (111) direction (Figure 22). Baskin (1975) reports ferrohastingsite from the Dore

Lake Complex, Chibougamau, and proposes the following reaction:

An alternate reaction, perhaps better suited to the formation of ferrohastingsite in the Opawica River Complex follows:

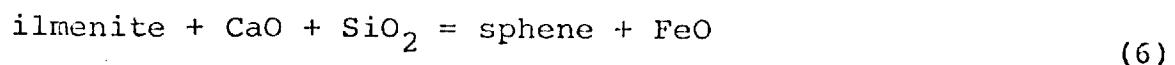

572.78 cc

567.45 cc

### Ilmenite

Ilmenite occurs as an "intercumulus" phase and, as previously discussed, as lamellae parallel to the (111) direction in magnetite. Sphene is observed as an alteration of ilmenite (Figure 23). The following reaction is proposed to explain the formation of sphene in the complex:

72.31 cc                    68.02 cc

Discussion

Winkler (1974) states that metamorphism is essentially an isochemical process. The preservation of original igneous structures and textures (Figures 6, 8, 10, 11, 12) in the rocks of the Opawica River Complex support this hypothesis, but these observations alone are not sufficient criteria to support isochemical metamorphism. Turner (1948) states neither bulk composition nor specific gravity of the rock remains constant during metasomatic metamorphism. Table 8 compares specific gravity of rocks from the Bushveld Complex and Stillwater Complex to those of the Opawica River Complex. These comparisons indicate that the specific gravity of rocks from the Opawica River Complex are basically unaffected by metamorphism. Postulated metamorphic reactions can be used as a criteria for isochemical metamorphism. In the written reactions for observed mineral assemblages in the Opawica River Complex the addition of components from outside the system is not necessary (reactions 1, 2, 3, 5, and 6).

Preservation of original igneous textures and structures, minor changes in specific gravity of the rocks and postulated metamorphic reactions suggest that metamorphism was essentially isochemical and isovolumetric with any migration of elements limited to a few millimeters.

## CHAPTER V

## ECONOMIC GEOLOGY

Exploration for base metal sulfide deposits of Archean to Tertiary age has become more sophisticated since the volcanogenic nature of many of these base metal deposits was recognized. Volcanogenic massive sulfide deposits have many similarities (Sangster, 1972). However, these are not the only important type deposits found in the Archean rocks of the Canadian Shield. Exploration in Archean rocks of the Canadian Shield should be directed toward mineral deposits having a magmatic origin with special attention given to ultramafic rocks and layered intrusions as well as toward the volcanogenic type deposits.

Magmatic Ore Deposits

Oxide and sulfide mineralization is known to occur as horizons in layered complexes. Chromite, vanadiferous magnetite, and sulfides of the platinum group minerals, copper and nickel, are found associated with layered complexes. Chromite and sulfide horizons are associated with mafic to ultramafic rocks (Cameron & Desborough, 1969, Bichan, 1969, Cousins, 1969, and Souch & Podalsky et al., 1969). Because these minerals occur at the same stratigraphic

horizons, exploration should be directed to ultramafic rocks associated with layered complexes. In the Opawica River Complex there is no exposed ultramafic zone. If an ultramafic zone exists, it would probably be located below the Opawica River Pluton. Vanadiferous magnetite is being mined from the Bushveld Complex. Magnetites from the Opawica River Complex have very similar chemistry to magnetites from the Bushveld Complex and Dore Lake Complex (Table 8). The magnetites occur in the Gabbro-Ferropyroroxenite Zone and are defined by a magnetic high. In the lithologies studied, magnetite comprised less than 25% of the rock by volume. The large amounts of glacial drift could, however, mask concentrations of magnetite similar to those in the Bushveld Complex. Hence, more work is necessary in order to determine if economic concentrations of magnetite are present.

#### Volcanogenic Ore Deposits

Syngenetic deposits are generally associated with a volcanic sequence tens of thousands of feet thick (Goodwin, 1968). The volcanic complex can be divided into three main portions: the lowermost part consists of pillow and vesiculated flows generally of basaltic composition, the second part consists of flows, flow breccias, and tuffs mostly of andesitic composition, and the upper most portion consists of flows and pyroclastics of dacitic to rhyolitic composition (Sangster, 1972). Another characteristic of these deposits is that the volcanic pile has been intruded

by rocks of varying compositions. Acid intrusions are the most common rock types associated with the volcanic pile (Sangster, 1972). However, the Chibougamau and Matagami areas are two notable exceptions in that they have layered intrusions in the volcanic core, as does the Opawica River area. These layered intrusions could represent volcanic centers. If there is a link between mineralization and layered intrusions, the volcanic rocks in La Ronciere, Guercheville, Gand, and Lesperance Townships should be considered as exploration targets for volcanogenic ore deposits. Within the Opawica River Complex, as in the Dore Lake Complex, mineralized shear zones could be expected to occur in the Anorthosite Zone, but no areas of intense alteration have been observed. However, one must remember that approximately 99% of the area is drift covered.

## CHAPTER VI

## SUMMARY

The Opawica River Complex is an Archean layered intrusion. It intruded discordantly volcanic rocks of the Matagami-Chibougamau Greenstone Belt. The volcanics and Opawica River Complex were intruded by the Opawica River Pluton, consisting mostly of biotite trondhjemite, and folded into an east-west trending anticline during the Kenoran Orogeny. The La Ronde Lake Pluton, a post-kinematic zoned granitic pluton, has intruded the Opawica River Complex and volcanics. The complex and enclosing volcanics have for the most part been metamorphosed to the quartz-albite-muscovite-chlorite subfacies of the greenschist facies. Original igneous structures and textures have been well preserved.

The Opawica River Complex is divided into two zones: Anorthosite Zone and the gabbro-Ferropyroxenite Zone. Due to the tilted nature of the original magma chamber and folding the Gabbro-Ferropyroxenite Zone is not continuous over the entire outcrop length of the complex.

The rocks are marked by an enrichment on FeO and depletion of MgO. The rocks are characterized by a high ratio of  $\text{Na}_2\text{O} : \text{K}_2\text{O}$ . The Opawica River Complex is the result of

fractional crystallization of a basaltic magma having tholeiitic affinities.

Similarities in geology with the Chibougamau and Matagami areas make the Opawica River-La Ronde Lake region an excellent exploration target for volcanogenic sulfide deposits. Also, one might expect to find magmatic ore deposits within the Opawica River Complex since layered complexes are known to contain deposits of this type.

APPENDIX I

Laboratory Procedures

## APPENDIX I

## LABORATORY PROCEDURES

Petrographic and Mineralogical Techniques

Several laboratory techniques were utilized to obtain petrographic and mineralogical data. Thin sections from approximately 100 rock samples were studied using a Zeiss petrographic microscope. Plagioclase compositions were determined with the microscope using F. C. Calkins' curves for sections perpendicular to X. Immersion oils and Tsuboi's curves for refractive indices of cleavage fragments (Kerr, 1959) were used on plagioclases from the Opawica River Complex.

Analyses of selected mineral specimens were obtained using a Materials Analysis Company 400S Electron Microanalyzer. Analyses were made on polished sections and polished thin sections which had been coated with a 250 $\text{\AA}$  carbon film using a Varian vacuum evaporator. An operating voltage of 15KV and a sample current of 0.05 microamps were used. An average of five spots on each sample were analyzed using twenty second counts and a beam diameter of five microns. Only background and drift corrections were made since standards were selected to be very similar to the unknowns.

Semi-quantitative analyses of all major elements for actinolites were obtained using a Canberra energy dispersive detection system composed of a lithium-drifted silicon crystal, and a broad-spectrum, multichannel analyzer. X-ray emission spectrographs were made for unknown and natural mineral standards. Data were collected in 100 second counts. Peak heights of all major elements in the standards were graphically plotted and a line of calibration drawn between corresponding elements of standards. Observed peak heights of elements in the unknowns were compared with this calibration to obtain oxide percentages.

#### Whole Rock Chemical Techniques

Major elements except sodium and magnesium were analyzed by x-ray fluorescence. A cylindrical teflon mill (McCrone micronizing mill; McCrone Research Corporation) filled with corundum cylinders was loaded with 4.000 grams of rock powder and 1.000 gram of cellulose. Standards were prepared in an identical manner to compensate for possible aluminum contamination. Ethyl alcohol was added to the mill and agitated 10 minutes. The resulting slurry was rinsed and dried. The dry material was placed in a pellet die and pressed at 20 tons into a solid, stable pellet.

Pellets were analyzed on a Phillips-Norelco x-ray fluorescence instrument (Model Number PN 3260). Pellets of USGS standards were used to construct working curves. A pellet of  $\text{SiO}_2$  was utilized as a blank for all elements

except silicon. An internal standard was analyzed at every fourth count to provide for drift corrections. Count time was 100 seconds. Drift and background corrections were made on all samples.

Sodium and magnesium analyses were obtained with a Model 303 Perkins-Elmer Atomic Absorption Spectrophotometer. Instrument settings were essentially those recommended by the manufacturer's handbook. Samples were prepared for chemical analysis employing the method developed by Medlin, Surh, and Bodkin (1969).

Ferrous iron determinations were made by the "Wilson method" as described in Jeffery (1970). The method consists of a back titration using ferrous ammonium sulfate with barium dipheylamine as an indicator. USGS sample W-1 was used as a standare.
